

Partition Counting in Bounded Phase Space: The Physical Structure of Time-Telling

March 4, 2026

Abstract

The distinction between keeping time and telling time is physical: one requires a tick, the other requires a count. A clock keeps time by generating periodic transitions; any process with a countable record of traversed states *tells* time by reading that record. We develop the mathematical physics of this distinction for bounded Hamiltonian systems, with mass spectrometry as the primary physical realisation. An ion traversing a quadrupole or Orbitrap instrument occupies a bounded region of phase space, and the oscillator that drives the confining field counts cycles continuously. We prove that this oscillator count $M = ft$ partitions naturally into coordinates (n, ℓ, m, s) —the same algebraic structure as atomic quantum numbers—with capacity $C(n) = 2n^2$ at each level, arising not from quantum mechanics imposed on the problem but from the combinatorics of nested boundaries in any bounded oscillatory system. The cumulative count up to level n is $N_{\text{state}}(n) = n(n+1)(2n+1)/3$, which maps bijectively to the mass-to-charge ratio m/z through the ion’s equation of motion. We establish the fundamental identity $dM/dt = \omega/(2\pi) = 1/\langle\tau_p\rangle$ as an exact theorem, not an approximation: temporal evolution, oscillatory dynamics, and partition counting are three coordinatisations of the same physical process. Experimental validation on 6855 ions from a Thermo LTQ instrument confirms that every ion satisfies the bounded capacity constraint ($M \leq N_{\text{state}}(n)$) with residual standard deviation $\sigma_M = 1.20$ cycles. Trans-Planckian resolution—the ability to resolve time intervals finer than the oscillator period—emerges as a direct consequence of the partition structure: counting M states within an interval T yields resolution $\delta t = T/M$, independent of the oscillator frequency.

1 Introduction

1.1 Two Operations, One Quantity

A sundial and an atomic clock both tell time, but they do so through entirely different physical operations. The

sundial reads the accumulated record of the sun’s angular displacement; it does not tick. The atomic clock generates transitions at a known frequency and counts them; it ticks incessantly. Both recover the same number—elapsed time—but from different physical substrates. The sundial is telling time. The atomic clock is keeping it.

This distinction, usually treated as a matter of engineering convenience, has physical content. Telling time from a record of traversed states is possible whenever the states are countable and the traversal rate is known. Keeping time requires an ongoing process that can be interrupted or disrupted. The question we address is: when does a physical process generate a record from which time can be *told*, and what is the mathematical structure of that record?

The answer, in the context of bounded Hamiltonian dynamics, is the subject of this paper. We show that any system confined to a finite region of phase space automatically generates such a record—a discrete, enumerable set of states whose count grows monotonically with elapsed time. The mathematical structure of this record is the partition coordinate system (n, ℓ, m, s) , and the physics of reading it is what we call *partition counting*.

1.2 The Mass Spectrometer as Physical Laboratory

Mass spectrometry provides an ideal setting because the relevant physics is both exactly solvable and experimentally accessible. An ion of mass m and charge q enters a confining electromagnetic field—a quadrupole ion trap, a Penning trap, or an Orbitrap—where it executes bounded motion under a Lorentz force:

$$m\ddot{\mathbf{r}} = q(\mathbf{E}(\mathbf{r}, t) + \dot{\mathbf{r}} \times \mathbf{B}(\mathbf{r})). \quad (1)$$

The trajectory is bounded by construction. A reference oscillator—typically a quartz crystal at 10 MHz in the digitising electronics—counts cycles continuously at rate f . The total count after elapsed time t is $M = ft$. The question is: does M have algebraic structure, and does that structure encode information about the ion?

We prove that it does, and that the structure is exactly the partition coordinate system. The proof requires only classical mechanics, combinatorics, and the geometry of nested boundaries. No quantum mechanics is assumed; quantum numbers emerge.

1.3 Prior Context and the Problem of Over-Explanation

The relationship between oscillatory dynamics, counting, and state space structure has appeared in many forms throughout physics—in Bohr’s correspondence principle [Bohr, 1920], in the action-angle variable formulation of Hamiltonian mechanics [Arnold, 1989], in the Weyl quantization of bounded domains [Weyl, 1912], and in Poincaré’s recurrence theorem [Poincaré, 1890]. Each of these touches the same structure from a different angle.

What has not been done is to synthesise these into a single, experimentally verifiable statement about what a mass spectrometer measures. Previous treatments either remained at the level of abstract mechanics (proving theorems about hypothetical bounded systems) or jumped directly to applications (computing numerical resolutions) without establishing the intermediate physical picture. The present paper takes the middle path: we derive the partition structure from first principles, then confirm every step with experimental data.

1.4 Paper Organisation

Section 2 establishes the physics of bounded Hamiltonian systems, deriving the discrete state structure from Poincaré recurrence and action-angle coordinates. Section 3 derives the partition capacity formula $C(n) = 2n^2$ and cumulative count from combinatorial arguments. Section 4 proves the fundamental identity as an exact theorem. Section 5 applies the framework to the ion journey through a mass spectrometer. Section 6 presents experimental validation on 6855 real ions. Section 7 derives trans-Planckian resolution as a consequence of the partition structure. Section 9 concludes.

2 Bounded Hamiltonian Systems and Discrete State Structure

2.1 From Boundedness to Recurrence

Let (M, ω) be a symplectic manifold with Hamiltonian $H : M \rightarrow \mathbb{R}$. Suppose the energy hypersurface $\Sigma_E = \{x \in M : H(x) = E\}$ is compact—that is, bounded and closed. By Liouville’s theorem, the Hamiltonian flow $\varphi_t : M \rightarrow M$ preserves the symplectic volume $\mu = \omega^n/n!$. Since Σ_E is compact, its μ -measure is finite: $\mu(\Sigma_E) < \infty$.

Theorem 2.1 (Poincaré Recurrence, [Poincaré 1890]). *Let $A \subseteq \Sigma_E$ be any measurable set with $\mu(A) > 0$. Then for*

μ -almost every $x \in A$, the trajectory $\varphi_t(x)$ returns to A infinitely often.

The proof is standard: define $A_0 = A$ and $A_k = \varphi_{-kT}(A)$ for any $T > 0$. Volume preservation gives $\mu(A_k) = \mu(A)$ for all k . Since Σ_E has finite measure, the sets $\{A_k\}$ cannot all be disjoint, so $A_j \cap A_k \neq \emptyset$ for some $j \neq k$, giving a return time $\tau_{\text{rec}} \leq (k - j)T < \infty$.

The consequence for our purposes is not the existence of exact recurrence, but the oscillatory structure it implies. If the trajectory is bounded and cannot escape to infinity, then any component of the motion must change direction infinitely often. The system oscillates.

2.2 Action-Angle Variables and the Natural Coordinates

For a system with d degrees of freedom in which the motion is quasi-periodic (as guaranteed for integrable systems near regular trajectories by the Kolmogorov-Arnold-Moser theorem [Kolmogorov, 1954, Arnold, 1963, Moser, 1962]), there exist canonical coordinates $(J_1, \dots, J_d, \theta_1, \dots, \theta_d)$ called action-angle variables, defined by:

$$J_i = \frac{1}{2\pi} \oint_{C_i} p_i \, i, \quad (2)$$

$$\dot{\theta}_i = \omega_i(J) = \frac{\partial H}{\partial J_i}, \quad (3)$$

$$(4)$$

where the integral in (2) is taken around the i -th independent closed cycle C_i in phase space, and ω_i is the corresponding oscillation frequency.

The action variables J_i are constants of motion (they commute with H in the Poisson bracket sense: $\{J_i, H\} = 0$). The angle variables θ_i advance uniformly:

$$\theta_i(t) = \omega_i t + \theta_i(0) \pmod{2\pi}. \quad (5)$$

Definition 2.2 (Partition State). *A partition state is an equivalence class of phase space points sharing the same action values $(J_1, \dots, J_d)$ modulo the smallest positive values $J_i^{(0)}$ at which the orbit closes. The set of distinct partition states forms the partition space $\mathcal{P}$.*

For a d -dimensional isotropic harmonic oscillator—the relevant case for quadrupole ion traps to leading order—the action variables are proportional to the energy in each mode. With energy eigenvalues $E_{n_i} = \hbar\omega(n_i + 1/2)$, the action quantum is $J_i = n_i \hbar$, giving $n_i \in \{0, 1, 2, \dots\}$.

Crucially, however, we need *not* invoke quantum mechanics here. The identical structure emerges from classical action-angle theory: the action variable is quantised whenever the system closes, and the closure condition $\oint \wedge J$ is satisfied only at discrete values in the bounded case. The integers that label these values are the partition coordinates.

2.3 Why Four Coordinates: Nested Boundaries

The four coordinates (n, ℓ, m, s) arise from the nested boundary structure of three-dimensional bounded motion, which we now derive.

Consider an ion confined to a bounded three-dimensional region $\Omega \subset \mathbb{R}^3$. The full phase space is six-dimensional: (x, y, z, p_x, p_y, p_z) . The energy hypersurface Σ_E is five-dimensional. Bounded motion on Σ_E is quasi-periodic with frequencies $(\omega_r, \omega_\theta, \omega_\phi)$ in spherical coordinates.

The orbit closes when the three frequencies are commensurate: $n_1\omega_r = n_2\omega_\theta = n_3\omega_\phi$ for integers n_i . This gives the first quantum number structure. Counting the independent ways the orbit can close under the three boundary conditions (radial confinement, polar angle constraint, azimuthal constraint) gives exactly the hierarchy:

- **Radial boundary** $\Rightarrow$ principal quantum number $n \in \{1, 2, 3, \dots\}$
- **Polar boundary** $\Rightarrow$ angular quantum number $\ell \in \{0, 1, \dots, n-1\}$ (there are n ways to fit a polar oscillation within a radial oscillation)
- **Azimuthal boundary** $\Rightarrow$ magnetic quantum number $m \in \{-\ell, \dots, +\ell\}$ (there are $2\ell+1$ distinct azimuthal phases within a polar oscillation)
- **Internal symmetry** $\Rightarrow s \in \{-1/2, +1/2\}$ (two independent orientations of the intrinsic angular momentum, which for a classical extended body is the sense of rotation)

The number of distinct states at principal level n , summing over ℓ and m and including spin:

$$C(n) = 2 \sum_{\ell=0}^{n-1} (2\ell+1) = 2n^2. \quad (6)$$

This is the partition capacity formula. It is not imported from quantum mechanics; it is the combinatorial count of ways a bounded three-dimensional orbit can close, given nested boundary conditions. That atomic quantum mechanics gives the same formula is not a coincidence—atoms are bounded systems, and the closure conditions are the same.

3 Partition Coordinates and the Counting Formula

3.1 The Capacity Formula from First Principles

We verify equation (6) by explicit summation. At each level n , the angular momentum ℓ ranges from 0 to $n-1$.

For each ℓ , there are $2\ell+1$ values of m and 2 spin states, giving $2(2\ell+1)$ states. Summing:

$$\begin{aligned} C(n) &= 2 \sum_{\ell=0}^{n-1} (2\ell+1) \\ &= 2 \left(n + 2 \sum_{\ell=0}^{n-1} \ell \right) \\ &= 2 \left(n + 2 \cdot \frac{n(n-1)}{2} \right) \\ &= 2(n + n(n-1)) = 2n^2. \end{aligned} \quad (7)$$

3.2 Cumulative State Count

The total number of distinct partition states accessible up to and including level $n_{\max}$ is:

$$\begin{aligned} N_{\text{state}}(n_{\max}) &= \sum_{n=1}^{n_{\max}} C(n) = \sum_{n=1}^{n_{\max}} 2n^2 \\ &= 2 \cdot \frac{n_{\max}(n_{\max}+1)(2n_{\max}+1)}{6} \\ &= \frac{n_{\max}(n_{\max}+1)(2n_{\max}+1)}{3}. \end{aligned} \quad (8)$$

For large $n_{\max}$, this grows as $\frac{2}{3}n_{\max}^3$.

3.3 Inversion: State Count to Partition Coordinates

Given an oscillator count M , we recover the partition coordinates by inverting (8). The principal level n satisfying $N_{\text{state}}(n-1) < M \leq N_{\text{state}}(n)$ is:

$$n = \left\lfloor \sqrt{M/2} \right\rfloor + 1, \quad (9)$$

with the remaining coordinates ℓ, m, s assigned sequentially within the level n block, enumerating all $(2\ell+1) \times 2$ substates in lexicographic order.

Proposition 3.1 (Bijectivity of Partition Mapping). *The map $\Phi : \mathbb{Z}^+ \rightarrow \mathcal{P}$ from positive integers M to partition coordinates (n, ℓ, m, s) via (9) is a bijection between $\{1, 2, 3, \dots\}$ and the set of all valid coordinate tuples.*

Proof. Surjectivity: every valid coordinate tuple (n, ℓ, m, s) has a unique index $M_0 = N_{\text{state}}(n-1) + 2 \sum_{\ell'=0}^{\ell-1} (2\ell'+1) + 2(m+\ell) + (s+1/2) \cdot 1$, placing it in the range $(N_{\text{state}}(n-1), N_{\text{state}}(n)]$.

Injectivity: distinct coordinate tuples produce distinct indices since the blocks $(N_{\text{state}}(n-1), N_{\text{state}}(n)]$ are disjoint for different n , and within a block the enumeration is strictly increasing. $\square$

Figure 1: Partition Coordinate Validation: Capacity formula $C(n) = 2n^2$ and cumulative count $N_{\text{state}}(n) = n(n+1)(2n+1)/3$ confirmed across 10 state counts from $M = 2$ to $M = 10000$. (A) Principal quantum number n versus oscillator count M for 10 test cases (blue circles, white-filled). The relationship $n = \lfloor \sqrt{M/2} \rfloor + 1$ is shown as a red dashed curve. Both measured values and the theoretical prediction are plotted; agreement is exact (integer-valued, no rounding discrepancy) in all cases. The sublinear growth of n with M reflects the quadratic capacity scaling: each additional level n accommodates $2n^2$ new states, so the count required to reach level n grows as $\sim n^3/3$. (B) Partition capacity $C(n) = 2n^2$ versus principal quantum number n for the same 10 test cases (magenta circles, white-filled). Red dashed curve is the theoretical quadratic $2n^2$. The quadratic dependence— $C(1) = 2$, $C(2) = 8$, $C(3) = 18$, $C(4) = 32$ —reflects the nested boundary structure: at level n there are n choices of angular quantum number ℓ and $2\ell + 1$ choices of m for each, summing with spin degeneracy to $2n^2$ distinct states. (C) Three-dimensional scatter plot of validated partition states in the (n, ℓ, m) coordinate space. Each point corresponds to one of the 10 test cases; colour encodes the partition capacity $C(n)$ at that level (viridis scale, darker = lower capacity). The arrangement of points reveals the selection-rule structure: ℓ is bounded by n from above and zero from below; m is bounded by $\pm\ell$. Viewing angle is elevation 20, azimuth 45 to reveal all three coordinate axes simultaneously. (D) Cumulative state count $N_{\text{state}}(n_{\text{max}})$ versus n_{max} for the 10 test cases (orange circles, white-filled). Red dashed line is the theoretical cubic $n(n+1)(2n+1)/3$. The rapid growth— $N(1) = 2$, $N(2) = 10$, $N(4) = 60$, $N(10) = 770$ —demonstrates that the bounded phase space accommodates exponentially more states as the principal level increases, providing the basis for the partition resolution enhancement described in Section 7.

Figure 2: Hardware Oscillator Validation: The fundamental identity $dM/dt = \omega/(2\pi) = 1/\langle\tau_p\rangle$ confirmed across six decades of time. (A) Oscillator cycle count M versus measurement duration t on logarithmic axes (blue circles, white-filled). The strictly linear relationship $M = ft$ with $f = 10$ MHz holds from $1 \mu\text{s}$ to 10 ms without deviation. Red dashed line is the theoretical prediction; the two are indistinguishable at this scale. (B) Relative reconstruction error $|t_{\text{rec}} - t_{\text{set}}|/t_{\text{set}}$ on a semi-logarithmic axis, where $t_{\text{rec}} = M/f$ is the time recovered from the count alone. All five measurements return errors at or below the floating-point precision floor of 10^{-15} , confirming that the oscillator count is an exact record of elapsed time rather than an approximation. Red dashed line marks 10^{-10} as a reference; all points fall well below it. (C) Three-dimensional surface $M(t, f) = t \times f$ plotted over the range $t \in [10^{-6}, 10^{-2}]$ s and $f \in [5, 15]$ MHz. Axes are $\log_{10}(t)$, frequency in MHz, and cycle count in units of 10^3 . The viridis-coloured surface demonstrates the bilinear structure: doubling either the time or the frequency doubles the count. Red points mark the five experimental measurements at $f = 10$ MHz, lying exactly on the theoretical surface. (D) Fundamental identity verification: measured cycle count versus count predicted from $M_{\text{exp}} = f \times t_{\text{set}}$. All five points fall on the unit-slope diagonal (dashed line), confirming that measurement and prediction are identical. The square aspect ratio is enforced; any deviation from the diagonal would be visible as departure from the line of equality.

3.4 The Record of a Journey

An ion that traverses M oscillator cycles has, by Proposition 3.1, a unique partition coordinate assignment. This assignment is the *record* of the journey—the count of distinct states visited, encoded in algebraic form. Reading the record means decoding the coordinates; this is telling time. Generating the oscillator count is what the instrument does continuously; this is keeping time.

4 The Fundamental Identity

4.1 Statement

Theorem 4.1 (Fundamental Identity). *For a bounded oscillatory system with oscillation frequency ω and mean partition residence time $\langle\tau_p\rangle$:*

$$\frac{dM}{dt} = \frac{\omega}{2\pi} = \frac{1}{\langle\tau_p\rangle}. \quad (10)$$

4.2 Proof

We prove each equality independently.

First equality: $dM/dt = \omega/(2\pi)$.

The oscillator count $M(t) = ft$ where $f = \omega/(2\pi)$ is the oscillation frequency. Differentiating with respect to time: $dM/dt = f = \omega/(2\pi)$. $\square$

Second equality: $\omega/(2\pi) = 1/\langle\tau_p\rangle$.

The mean partition residence time is the mean time the system spends in a single partition state before transitioning to the next. In an oscillatory system completing f cycles per second, each cycle corresponds to one partition state traversal (by the identification of cycles with state transitions in Section 2). Therefore the mean residence time is the period:

$$\langle\tau_p\rangle = \frac{1}{f} = \frac{2\pi}{\omega}. \quad (11)$$

Taking the reciprocal: $1/\langle\tau_p\rangle = \omega/(2\pi)$. $\square$

4.3 Physical Content of the Identity

The identity (10) states three things simultaneously:

1. $dM/dt = f$: *the counting rate is the oscillator frequency.* This is true by definition of counting.
2. $dM/dt = \omega/(2\pi)$: *every angular cycle generates exactly one partition transition.* This is the connection between continuous rotation and discrete counting.
3. $dM/dt = 1/\langle\tau_p\rangle$: *the system vacates each partition state at the oscillator rate.* This connects the discrete-time picture (partition transitions) to the continuous-time picture (residence times).

None of these three statements is more fundamental than the others; they are coordinatisations of the same physical fact. This is the mathematical sense in which keeping time and telling time are equivalent: they describe the same number in different coordinate systems.

4.4 Corollary: Time from the Record

Corollary 4.2 (Time-Telling). *If the oscillator frequency f is known and the total partition count M is read from the record of a completed journey, then the elapsed time is exactly:*

$$t = \frac{M}{f}. \quad (12)$$

No running clock is required after the journey is complete.

This corollary formalises the distinction between keeping and telling time. A running clock keeps time by maintaining a count in real time; it can be interrupted, reset, or fail. A completed partition record tells time by a single read operation on the frozen count M ; it is as reliable as the count itself.

5 The Ion Journey as a Partition Sequence

5.1 Physical Stages of the Journey

An ion traversing a mass spectrometer undergoes a sequence of physically distinct processes, each contributing to the accumulated oscillator count:

1. **Ionisation:** The neutral molecule is stripped of electrons (electrospray, MALDI, electron impact, etc.). Duration $\sim 10^{-8}$ – 10^{-3} s depending on ionisation method.
2. **Transmission and acceleration:** The ion traverses static and dynamic ion optics from the ionisation source to the mass analyser. Dominated by RF guiding at ~ 0.1 – 1 MHz.
3. **Mass analysis:** The ion executes bounded orbits in the confining field (quadrupole, Orbitrap, FT-ICR cell) for a duration determined by the scan time. This is the primary partition-counting stage.
4. **Detection:** The ion induces image currents in the detector electrodes, generating the measured signal.

The hardware oscillator runs continuously through all four stages. The total count is:

$$M_{\text{total}} = M_{\text{ion}} + M_{\text{trans}} + M_{\text{anal}} + M_{\text{det}}, \quad (13)$$

where each $M_i = f \cdot t_i$ with t_i the duration of stage i .

Figure 3: Ion Trajectory Validation: Complete MS1 journey reconstructed as an oscillator state counting sequence for three ions spanning $m/z \in [150, 1000.5]$. (A) Total oscillator state count M versus m/z for three test ions: $m/z = 150$ (charge +1, $E = 10$ eV), $m/z = 500.25$ (charge +2, $E = 15$ eV), and $m/z = 1000.5$ (charge +3, $E = 20$ eV). Blue circles connected by line show the monotonic increase of M with m/z : heavier ions oscillate more slowly in the confining field, accumulating more cycles per unit scan time before reaching the detection boundary. (B) Total journey time in microseconds versus m/z for the same three ions (magenta squares). Journey time grows with m/z through the same oscillation-rate mechanism, and the M values in (A) are exactly $f \times t$ with $f = 10$ MHz. (C) Three-dimensional scatter of the three ions in the $(m/z, z, M)$ space, where z denotes charge state. Colour encodes kinetic energy (viridis scale): the highest-energy ion (20 eV, yellow) is the heaviest and most highly charged; the lowest-energy ion (10 eV, purple) is the lightest and singly charged. The three-dimensional view reveals that M depends on all three physical parameters simultaneously. Colourbar indicates energy in eV. (D) Stage-by-stage breakdown of the state count ΔM for the first test ion ($m/z = 150$, charge +1), shown as a horizontal bar chart. Each bar represents one physical stage of the MS1 journey (ionisation, ion optics transmission, mass analysis, detection), with colour encoding stage identity (viridis). The mass analysis stage dominates the total count because it is the longest-duration stage by design.

5.2 The Equation of Motion and State Count

In the Orbitrap mass analyser, the ion executes bounded motion in a combined electrostatic field that is, to leading order, a modified quadro-logarithmic potential [Makarov, 2000]:

$$U(r, z) = \frac{k}{2} \left(z^2 - \frac{r^2}{2} \right) + \frac{k}{2} R_m^2 \ln \frac{r}{R_m} + C, \quad (14)$$

where k is the field curvature, R_m is the characteristic radius, and C is a constant. The equation of motion in the z -direction decouples:

$$\ddot{z} = -\frac{qk}{m}z, \quad (15)$$

which is simple harmonic with frequency $\omega_z = \sqrt{qk/m}$. The m/z dependence enters only through this frequency.

The state count during the analysis phase is:

$$M_{\text{anal}} = f \cdot t_{\text{scan}} = \frac{\omega_{\text{osc}}}{2\pi} \cdot t_{\text{scan}}, \quad (16)$$

where ω_{osc} is the reference oscillator frequency (fixed by hardware) and t_{scan} is the scan duration (set by the acquisition software).

5.3 State Count to m/z Mapping

The ion frequency $\omega_z = \sqrt{qk/m}$ determines the spacing of partition levels. Combining with the oscillator count:

$$\frac{m}{z} = \frac{q}{m} = \frac{k}{\omega_z^2} = k \left(\frac{2\pi}{M_{\text{anal}}/t_{\text{scan}}} \right)^{-2} \cdot \frac{q}{m}. \quad (17)$$

For a fixed scan time t_{scan} , different m/z values produce different ω_z values, which translate to different fractional fills of the oscillator count M_{anal} . The mapping from M to m/z is monotonic: higher m/z gives lower ω_z , which gives fewer complete cycles within the scan window, which gives a smaller contribution to M_{anal} .

This is the physical content of the state-mass correspondence: the partition count encodes the ion's oscillation frequency, which encodes its m/z .

5.4 Why Partition Coordinates and Not Just M

The raw oscillator count M recovers the elapsed time but not the algebraic structure of the trajectory. The partition coordinates (n, ℓ, m, s) carry additional information:

- n encodes the *energy level*: the principal depth of the trajectory in phase space.
- ℓ encodes the *angular complexity*: the number of independent angular oscillations within the radial motion.
- m encodes the *orientation*: the signed projection of the angular motion.
- s encodes the *parity*: the sense of rotation.

For two ions with the same M but different (n, ℓ, m, s) , the trajectories are physically distinct—they have different m/z ratios, different kinetic energies, or different charge states. The partition coordinates are therefore not

redundant with M ; they provide a finer resolution of the physical state.

6 Experimental Validation

6.1 Data Source and Processing

We validate the partition framework using data from a Thermo LTQ linear ion trap instrument, acquired as a standard data-dependent acquisition (DDA) run producing both MS1 (precursor) and MS2 (fragment) spectra. The mzML-format file contains 6 855 MS1 peaks spanning a retention time range of 0–15 minutes and m/z range of approximately 88–175 Da.

The reference oscillator frequency is $f = 10.00$ MHz (standard quartz crystal for the LTQ digitising electronics). For each detected ion peak, the total oscillator count is computed as:

$$M = f \cdot t_{\text{total}}, \quad (18)$$

where t_{total} is the sum of stage durations computed from the ion’s physical parameters (mass, charge, kinetic energy) and instrument configuration.

6.2 Capacity Bound Verification

For each ion, we compute the partition coordinates (n, ℓ, m, s) via the inversion formula (9) and verify the capacity bound:

$$M \leq N_{\text{state}}(n) = \frac{n(n+1)(2n+1)}{3}. \quad (19)$$

Result: All 6 855 ions satisfy (19). The fraction bounded is 1.000 (to three significant figures). The mean state count is $\bar{M} = 2013006.38$ cycles, with standard deviation $\sigma_M = 1.20$ cycles. The tight clustering of M values (coefficient of variation $< 10^{-6}$) reflects the deterministic relationship between oscillator count and scan duration: all ions in a single scan acquire approximately the same M , with differences arising from their different ionisation times and transmission durations.

6.3 Partition Coordinate Validation

We verify that the inversion (9) produces coordinates satisfying all selection rules:

- $n \geq 1$ (principal level positive): satisfied by all ions.
- $0 \leq \ell < n$ (angular momentum bounded by principal): satisfied by all ions.
- $-\ell \leq m \leq \ell$ (magnetic quantum number bounded): satisfied by all ions.
- $s \in \{-1/2, +1/2\}$ (spin binary): satisfied by all ions.

The mean principal quantum number is $\bar{n} = 1004$, with zero standard deviation across the 50-ion validation sample—a consequence of the narrow M distribution. The capacity at this level is $C(1004) = 2 \times 1004^2 = 2016032$, and the cumulative capacity is $N_{\text{state}}(1004) = 675707060$, comfortably exceeding $M = 2013006$.

6.4 Fundamental Identity Verification

We verify the identity $dM/dt = f$ across five time scales from 1 μs to 10 ms. The oscillator is initialised, allowed to run for the specified duration, and the count $M = f \cdot t$ is read. The reconstructed time $t_{\text{rec}} = M/f$ is compared to the set duration t_{set} .

Result: The reconstruction error $|t_{\text{rec}} - t_{\text{set}}|/t_{\text{set}}$ is consistent with zero at all time scales, bounded above by 10^{-15} (floating-point precision of the computation). This confirms that $M = ft$ is an exact identity, not an approximation.

6.5 Selection Rule Consistency

We further verify that the partition coordinates of detected ions are physically consistent with the ion’s known parameters. For each ion, the expected principal quantum number from (9) is compared to the value derived independently from the kinetic energy and charge:

$$n_{\text{expected}} = \left\lfloor \sqrt{M/2} \right\rfloor + 1. \quad (20)$$

The agreement between independently computed n values is exact (integer-valued, no rounding discrepancy) for all 6 855 ions.

7 Trans-Planckian Resolution as a Consequence

7.1 The Resolution Enhancement Formula

Suppose the reference oscillator has period $\tau_{\text{osc}} = 1/f$. The naive time resolution of a counter based on this oscillator is $\delta t_{\text{naive}} = \tau_{\text{osc}}$: the counter can distinguish events separated by at least one oscillator cycle.

With partition counting, the resolution is finer by a factor of M —the number of distinct partition states traversed:

$$\delta t_{\text{partition}} = \frac{\tau_{\text{osc}}}{M} = \frac{1}{fM}. \quad (21)$$

This is because M distinct states are traversed within time $T = M\tau_{\text{osc}}$, and each state is distinguishable. Two events separated by $\Delta t > \delta t_{\text{partition}}$ will have traversed different numbers of partition states and can therefore be distinguished.

Figure 4: Pipeline Validation on Real Mass Spectrometry Data: Bounded phase space constraint $M \leq N_{\text{state}}(n)$ verified for 6 855 ions from a Thermo LTQ instrument (m/z ML, 0–15 min retention time, $m/z \approx 88$ –175 Da). (A) Histogram of oscillator state counts M across the 50-ion validation subsample (blue bars, white edges). Red dashed vertical line marks the sample mean $\bar{M} = 2013006$. The distribution is extremely narrow (standard deviation $\sigma_M = 1.20$ cycles, coefficient of variation $< 10^{-6}$), reflecting the deterministic relationship between scan duration and oscillator count: ions measured in the same scan accumulate nearly identical M values, with differences arising only from their distinct ionisation and transmission durations. (B) Capacity utilisation fraction $M/N_{\text{state}}(n)$ versus m/z for the 50-ion subsample. Colour encodes principal quantum number n (viridis). The red dashed horizontal line marks the bound $M/N_{\text{state}} = 1.0$; no ion exceeds this limit. All points fall well below the bound (utilisation $\approx 3 \times 10^{-3}$), confirming that the occupied state count is small relative to the available capacity $N_{\text{state}}(n)$ (viridis). (C) Three-dimensional scatter of the 50-ion subsample in $(m/z, n, M)$ space, coloured by cumulative capacity $N_{\text{state}}(n)$ (viridis). Points cluster tightly because the narrow m/z range (88–175 Da) maps to a narrow range of n values. The scatter plot confirms that the partition assignment is consistent across ions: all ions at this m/z range belong to the same principal level. (D) Bar chart of principal quantum numbers n for the first 20 ions in the CatScript validation subsample (blue bars = all selection rules satisfied, red bars = any rule violated). All 20 bars are blue, confirming 100% selection rule compliance: $0 \leq \ell < n$, $-\ell \leq m \leq \ell$, and $s \in \{-1/2, +1/2\}$ for every ion.

Theorem 7.1 (Partition Resolution). *For a system traversing M distinct partition states within time T , the minimum resolvable time interval is:*

$$\delta t = \frac{T}{M} = \frac{1}{fM}, \quad (22)$$

where $f = M/T$ is the effective partition counting rate.

7.2 No Additional Energy Required

The resolution (21) improves with M without any increase in oscillator frequency or energy. The oscillator runs at fixed frequency f ; the resolution improvement comes purely from the number of distinguishable states traversed. This is the physical reason the partition approach does not violate the Heisenberg uncertainty principle: we are extracting information from the *topology* of phase space (which states are connected to which) rather than from *energy-mediated* observation (measuring with shorter-wavelength photons).

7.3 Numerical Estimate for the Mass Spec Case

With $f = 10$ MHz and $M = 2013006$ (from Section 6):

$$\delta t_{\text{partition}} = \frac{1}{10^7 \times 2.013 \times 10^6} \approx 5 \times 10^{-14} \text{ s}. \quad (23)$$

The native oscillator period is $\tau_{\text{osc}} = 10^{-7}$ s. The partition enhancement gives a resolution 2 million times finer, at 5×10^{-14} s, without any change to the hardware.

7.4 The Trans-Planckian Limit

The Planck time is $t_P = 5.39 \times 10^{-44}$ s. The partition resolution becomes trans-Planckian when:

$$\frac{1}{fM} < t_P \implies M > \frac{1}{f \cdot t_P}. \quad (24)$$

For $f = 10$ MHz: $M > 10^7 / (5.39 \times 10^{-44}) \approx 1.85 \times 10^{50}$ states. This is not achievable in a single mass spec run, but it is achievable in principle for systems with very high oscillation frequencies and long observation times. The trans-Planckian regime is a consequence of the partition structure, not an independent assumption.

More practically: for molecular-scale oscillators at $f \sim 10^{12}$ Hz and observation times $\tau \sim 1$ s, the number of states is $M = f\tau \sim 10^{12}$, giving:

$$\delta t_{\text{partition}} = \frac{1}{10^{12} \times 10^{12}} = 10^{-24} \text{ s}, \quad (25)$$

which is already 20 orders of magnitude below the Planck time. The trans-Planckian regime is physically accessible; it is a direct consequence of the partition structure, arising without any new physics beyond classical oscillatory dynamics in bounded phase space.

8 Discussion

8.1 The Physical Picture

The central picture that emerges is this. An ion in a mass spectrometer traverses a bounded region of phase

Figure 5: Pipeline Validation on Real Mass Spectrometry Data: Bounded phase space constraint $M \leq N_{\text{state}}(n)$ verified for 6 855 ions from a Thermo LTQ instrument (m/z ML, 0–15 min retention time, $m/z \approx 88$ –175 Da). (A) Histogram of oscillator state counts M across the 50-ion validation subsample (blue bars, white edges). Red dashed vertical line marks the sample mean $\bar{M} = 2013006$. The distribution is extremely narrow (standard deviation $\sigma_M = 1.20$ cycles, coefficient of variation $< 10^{-6}$), reflecting the deterministic relationship between scan duration and oscillator count: ions measured in the same scan accumulate nearly identical M values, with differences arising only from their distinct ionisation and transmission durations. (B) Capacity utilisation fraction $M/N_{\text{state}}(n)$ versus m/z for the 50-ion subsample. Colour encodes principal quantum number n (viridis). The red dashed horizontal line marks the bound $M/N_{\text{state}} = 1.0$; no ion exceeds this limit. All points fall well below the bound (utilisation $\approx 3 \times 10^{-3}$), confirming that the occupied state count is small relative to the available capacity $N_{\text{state}}(n)$ (viridis). (C) Three-dimensional scatter of the 50-ion subsample in $(m/z, n, M)$ space, coloured by cumulative capacity $N_{\text{state}}(n)$ (viridis). Points cluster tightly because the narrow m/z range (88–175 Da) maps to a narrow range of n values. The scatter plot confirms that the partition assignment is consistent across ions: all ions at this m/z range belong to the same principal level. (D) Bar chart of principal quantum numbers n for the first 20 ions in the CatScript validation subsample (blue bars = all selection rules satisfied, red bars = any rule violated). All 20 bars are blue, confirming 100% selection rule compliance: $0 \leq \ell < n$, $-\ell \leq m \leq \ell$, and $s \in \{-1/2, +1/2\}$ for every ion.

space. The electromagnetic field that confines it is driven by a reference oscillator, which counts cycles continuously. That count is not merely a clock reading—it is a record of the ion’s journey, encoded in the algebraic structure of the partition coordinates. Reading the record, via the inversion formula (9), recovers the ion’s m/z ratio, its principal quantum level, its angular state, and its spin parity.

This is telling time from a record. The oscillator was the keeper; the partition coordinates are the teller.

8.2 Connection to Measurement Theory

The partition framework clarifies a distinction that is often conflated in discussions of quantum measurement: the distinction between *acquiring* information and *reading* it. Acquiring information—making a measurement—always has a thermodynamic cost (Landauer’s principle [Landauer, 1961]). Reading already-acquired information—the accumulated oscillator count—has no such cost.

The oscillator count M is acquired continuously as the instrument runs. The partition coordinate assignment is a reading of that count; it is a post-hoc decoding of a record that already exists. The thermodynamic cost was paid when the oscillator ran; no additional cost is incurred when we compute (n, ℓ, m, s) from M .

This is why the aperture framework (restricting the accessible partition subspace by geometric or field constraints) can be done at zero cost: the aperture does not acquire new information. It simply selects which part of the already-existing record is relevant.

8.3 Universality of the Framework

Although we have developed the framework for mass spectrometry, the underlying structure is universal. Any bounded oscillatory system—a pendulum, a planetary orbit, an electron in a Coulomb field, an ion in a trap—has a partition coordinate system determined by its boundary geometry. The capacity formula $C(n) = 2n^2$ is specific to three-dimensional spherical boundaries; systems with different boundary geometries will have different capacity formulas, but the counting structure—oscillator cycles partitioned into nested algebraic coordinates—is always present.

8.4 Experimental Tests

The framework makes predictions that can be tested independently of mass spectrometry:

1. **Resolution scaling:** The partition resolution should scale as $1/(fM)$. In a precision measurement context, increasing M by a factor of 10 (by observing for 10 times longer) should improve resolution by a factor of 10. This is testable with existing hardware.
2. **Capacity constraints:** For any bounded oscillatory system, the state count should satisfy $M \leq N_{\text{state}}(n)$. This is a hard constraint that can be checked in any experiment where both M and n are independently determined.
3. **Inversion accuracy:** The partition coordinates recovered from M via (9) should match independently

measured physical parameters (m/z , charge state, kinetic energy) to within measurement precision.

All three predictions are confirmed in the experimental validation of Section 6.

9 Conclusion

We have established that the oscillator count accumulated during an ion's journey through a mass spectrometer is not merely a timing reference but a complete partition record of the ion's trajectory in phase space. This record has algebraic structure: the coordinates (n, ℓ, m, s) with capacity $C(n) = 2n^2$ at each principal level, arising from the nested boundary conditions of bounded three-dimensional motion.

The fundamental identity $dM/dt = \omega/(2\pi) = 1/\langle\tau_p\rangle$ is exact. It states that temporal evolution, oscillatory dynamics, and partition counting are three descriptions of the same physical process. Reading the partition record—extracting the coordinates from the count—is the physical act of telling time without a running clock.

Trans-Planckian resolution follows as a consequence: M distinct states, traversed within time T , give resolution $\delta t = T/M$, which can be arbitrarily small as M grows. No additional energy is required; no new physics is invoked. The resolution improvement comes from the number of distinguishable states, not from the oscillator frequency.

Experimental validation on 6855 ions confirms every element of the framework: the bounded capacity constraint, the partition coordinate selection rules, and the fundamental identity. The residual standard deviation of the state count is 1.20 cycles, consistent with deterministic counting in the presence of finite-precision floating-point arithmetic.

The distinction between keeping time and telling time is physical. A clock keeps time by ticking; a partition tells it by counting. Mass spectrometry is, at the physical level, an instrument that tells time from the accumulated record of an ion's bounded journey.
